ABSTRACT

Fabrication of three-dimensional (3D) objects through direct deposition of functional materials using 3D printing equipment is called additive manufacturing (AM). Benefits of AM include producing goods quickly and on-demand, with greater customization and complexity and less material waste. While the use of AM has been growing, a number of challenges continue to impede its more widespread adoption, particularly in the areas of non-destructive evaluation/non-destructive testing (NDE/NDT) techniques for AM equipment health monitoring and measurement. In this paper, a prognostics and health management (PHM) approach to AM equipment health monitoring, fault diagnosis and quality control is presented and illustrated with a case study. The presented PHM approach is developed using two types of NDE/NDT sensors: acoustic emission (AE) sensor and piezoelectric strain sensor. A seeded driving belt fault on a fused filament fabrication desktop 3D printer is used to validate the feasibility of the PHM approach in the case study. The case study results have shown the effectiveness of the presented method for AM equipment fault diagnosis and quality control.

1. INTRODUCTION

In his 2013 state of the union address, US President Obama called three-dimensional (3D) printing “the potential to revolutionize the way we make almost everything” (Office of the Press Secretary, 2013). Fabrication of 3D objects through direct deposition of functional materials using 3D printing equipment is called additive manufacturing (AM). Benefits of AM include producing goods quickly and on-demand, with greater customization and complexity and less material waste. If the modern manufacturing which was subtractive process by cutting or milling is optimized at mass production, the future manufacturing would be called a creative customization through 3D printing at consumers’ will.

While the use of AM has been growing, a number of challenges continue to impede its more widespread adoption, particularly in the areas of non-destructive evaluation/non-destructive testing (NDE/NDT) techniques for AM equipment health monitoring and measurement. According to a recent report on measurement science roadmap for metal-based additive manufacturing (Energetics Incorporated, 2013), current technical barriers or challenges in AM were roughly categorized as materials, process and equipment, qualification and certification, and modeling and simulation. Particularly in the process and equipment category, the highest priority in NDE/NDT techniques have been specified as: (1) Combining NDE techniques to better assess quality via an integrated approach; (2) Adapting existing NDE techniques to AM, especially parts, and characterizing defects; (3) Lack of affordable quality inspection tools for direct metal parts. Even though the 3D printing technology has been available since 80s, it was not until recent days that 3D printing came to the fore in commercial manufacturing. Thus, very few studies have been conducted on NDE based 3D printer health monitoring and prognostics. The AM has two unique characteristics: (1) relatively long cycle time; (2) high quality standard for dimension accuracy. These unique characteristics of AM can be considered as good opportunities for developing PHM based approach for 3D printer health monitoring, fault detection and quality control. As the dimension accuracy of the printed product can be caused by inaccurate movement of the 3D printer, by detecting the 3D printer fault and stopping the faulty execution of the printing process, manufacturing time, materials, and cost can be saved and product quality assured.

In the related field of rotating machinery fault detection and diagnostics, the use of different NDE/NDT techniques such as acoustic emission (Yoshioka and Fujiwara, 1984; Tandon and Mata, 1999; Tandon and Narka, 2000; Scheer et al.,

Jae Yoon et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 United States License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.
torsional vibration (Feng & Zuo, 2013), and fiber optic strain sensors (Kiddy et al., 2011) has been investigated with drivetrain in wind turbine and rotorcraft. In this study, the potential capability of acoustic emission (AE) and piezoelectric (PE) strain sensors as fault detection and quality control technique for AM equipment and product is investigated.

AE is commonly defined as transient elastic waves within a material, caused by the release of localized stress energy (Mathews, 1983). The advantage of using AE sensor as failure analysis source is that AE propagates from the epicenter to sensing apparatus within materials while vibration sensor requires perpendicular installation along with the vibration direction. Identifying vibration direction is sometimes painful if their sources are combinative. Also, AE signals are distinguishable from acoustic signals in that acoustic signals generally lie on the audible range of human (e.g. 20 Hz ~ 20 kHz). On the other hand, AE signals lie on a higher frequency range (e.g. 1 kHz ~ 1 MHz). Thus a high sampling rate between 2 to 10 MHz has been a typical choice of sampling rate for AE data collection. Other issues may arise including a high data volume and complicated feature of AE signals, which make the AE data processing challenging. However, it has been also reported that AE sensors are more sensitive in early fault detection than vibration sensors with various gear and bearing fault diagnostic applications (Yoshioka and Fujiwara, 1984; Tandon and Mata, 1999; Tandon and Narka, 2000; and Scheer et al., 2007).

The feasibility of using fiber optic strain sensors to detect damaged gearbox was recently reported by Kiddy et al. (2011). In their study, fiber optic strain sensors were mounted on a helicopter transmission test rig to investigate the detectability of gear fault conditions. However, the low maximum sampling rate (up to 1 kHz) of the fiber optic strain sensor limits its wide applicability in machinery fault detection. On the other hand, the PE strain sensors measure torsional vibration by quantifying terminal voltage difference released by deformed piezoelectric material. Unlike the fiber optic strain sensor, PE strain sensor has a merit in higher sampling rate up to 100 kHz. Compared to the conventional strain gauge sensors and accelerometers, the PE strain sensors have certain advantages that could be summarized as follows: (1) ability to measure the first derivative of physical deformation, (2) high linearity and sensitivity from their superior noise immunity as compared to differentiated sensing performance of conventional strain sensors (Lee and O’Sullivan, 1991; Banaszak 2001), (3) high frequency range (Jiang et al., 2014), (4) space-efficiency without a structural change on the measuring target (Kon et al., 2007), and (5) negligible temperature effect on the measurement output (Sirohi and Chopra, 2000; Jiang et al., 2014). The aforementioned benefits allow PE strain sensors to potentially have greater sensing resolution and accuracy.

Up to today, no investigation on 3D printer health monitoring and fault diagnosis has been reported in the literature. In this paper, an investigation into the feasibility of PHM based AE and PE strain signal analysis techniques for 3D printer fault detection and quality control is reported. The remainder of the paper is organized as follows. Section 2 provides a detailed explanation of the proposed methodology. In Section 3, the details of the experimental setup and the seeded fault tests on a 3D printer test rig for validating the proposed methodology are provided. Section 4 presents the 3D printer fault detection results from the seeded fault tests. Finally, Section 5 concludes the paper.

2. METHODOLOGY

An overview of the proposed methodology is provided in Figure 1. As shown in Figure 1, a data acquisition (DAQ) system is used to collect the AE signals and PE strain signals at the same time. While the PE sensor is directly connected to the DAQ, the AE sensor, on the other hands, is connected to the DAQ board through a hardware based heterodyne frequency reduction device. Then, filter bands are chosen for each sensor to remove noise in the collected signals before they can be used to compute condition indicators (CIs) for fault detection. The key components of the methodology are explained in the next two sections. Section 2.1 provides a brief review of the hardware based heterodyne technique for AE sensor and the computation of CIs for 3D printer fault detection is followed in Section 2.2.
2.1. The Heterodyne Technique

To apply AE based NDE/NDT techniques to machine fault detection and diagnosis, one technical challenge is to deal with the data storage and processing burden caused by the typical high sampling rate of AE sensor (from several MHz to 10 MHz). To meet the challenge, frequency shifting technique, namely heterodyne (Fessenden, 1913) based AE fault detection and diagnosis methods have been developed for gearboxes (Bechhoefer et al., 2013; Qu et al., 2013; 2014). The heterodyne technique downshifts the frequency of the AE signals so that a sampling rate comparable to vibration analysis can be utilized. From Eq. (5), it can be concluded that only the second term \( \frac{1}{2} m X_m \cos(2\omega_c \cdot t) \) will remain after applying low pass filter, while the high frequency components around frequency \( 2\omega_c \) will be removed. In the final heterodyning demodulation step, the signal frequency can be reduced to 10s of kHz. The resulting frequency range for AE signals becomes comparable to that of typical vibration signals. Thus, a lower sampling rate in an AE data acquisition system can be used. The heterodyned AE data acquisition procedure is shown by comparing it with the conventional AE methods in Figure 2.

Substituting Eq. (3) into Eq. (4) yields:

\[
U_o = \left( U_m + \frac{1}{2} m X_m \cos(\omega_c \cdot t) \right) \left( \frac{1}{2} \cos(2\omega_c \cdot t) \right)
\]

(5)

Finding a proper reference signal is critical to the successful implementation of the heterodyne technique in AE data acquisition. Since each AE sensor product from varying manufacturers has a unique frequency characteristic, the following optimization process based a linear chirp function is performed so that the root mean square (RMS) of the demodulated output signal could be maximized. The optimization process is described in Qu et al. (2014).

2.2. CIs for 3D Printer Fault Detection

Table 1 provides the definitions of CIs investigated for 3D printer fault detection in this paper. The CIs can be defined into five general types: root mean square (RMS), peak to

\[
U_o = \left( U_m + \frac{1}{2} m X_m \cos(\omega_c \cdot t) \right) \left( \frac{1}{2} \cos(2\omega_c \cdot t) \right)
\]

### Figure 2: Comparison of the heterodyned and conventional AE data acquisition procedures

Finding a proper reference signal is critical to the successful implementation of the heterodyne technique in AE data acquisition. Since each AE sensor product from varying manufacturers has a unique frequency characteristic, the following optimization process based a linear chirp function is performed so that the root mean square (RMS) of the demodulated output signal could be maximized. The optimization process is described in Qu et al. (2014).

</tr>
</tbody>
</table>

Note: $x_i$ is the $i^{th}$ element of the input data $x_{in}$; $N$ is the length of the input data $x_{in}$; $\max(\cdot)$ returns the maximal element of input data $x_{in}$; $\min(\cdot)$ returns the minimal element of input data $x_{in}$; $\overline{x}$ is a mean value of the input data $x_{in}$ defined as $\sum_{i=1}^{N} x_i / N$.

peak (P2P), skewness (SK), kurtosis (KT), and crest factor (CF). Each type of CI can be computed using different input signals. In addition to raw signals, other types of input signals can be generated: energy operator (EO), narrow band (NB), AM, and FM. The EO introduced by Teager (1992) is defined as the residual of the autocorrelation function as following:

$$x_{EO_i} = x_i^2 - x_{i-1} \cdot x_{i+1}, \quad (\text{for } i = 2, 3, \ldots, N - 1)$$ (6)

where $x_{EO_i}$ is the $i^{th}$ element of EO data; $x_i$ is the $i^{th}$ element of the input data $x_{in}$. NB is the time domain representation after applying narrow band of interest which could be seen in frequency domain. Finally, AM and FM are obtained by amplitude modulation and phase modulation of the NB filtered data.

3. EXPERIMENTAL SETUP

This section covers the experimental setup used to establish the AE and PE strain sensor based 3D printer fault diagnosis technique. The methodologies were validated with a desktop 3D printer using fused filament fabrication. Section 3.1 introduces the 3D printer test rig and Section 3.2 covers the seeded fault test.

3.1. The 3D Printer Test Rig

Figure 3 shows the 3D printer test rig and the DAQ system used in the seeded fault test in this paper.
The 3D printer test rig and the DAQ system.

The 3D printer test rig composes two main parts: (1) heterodyned AE based DAQ system, (2) 3D printer. The DAQ system includes a National Instruments' DAQ board with a maximum analog input sampling rate of 1.25 MHz, AE sensor attached on the 3D printer, demodulation board (AD8339), analog amplifier with gain 20/40/60dB, and function generator. The 3D printer (Makerbot, 2014) has a layer resolution up to $100 \mu m$, position precision of $11 \mu m$ on $X$ and $Y$ axes and $2.5 \mu m$ on $Z$ axis, and a nozzle of 0.4 mm diameter controlled by two stepper motors and wear resistant oil-infused bronze bearings.

### 3.2. 3D Printer Seeded Fault

According to the troubleshooting maintenance document (Makerbot, 2014) of the machine, one potential problem is the looseness of the belt driving the motion of the extruder nozzle. Thus, a malfunctioned toothed belt scenario was artificially created and simulated in this paper. The seeded fault was created by inserting five small pieces of metal wire into the slots between teeth of belt to create faulty operation during printing process. Figure 4 shows the seeded fault created by inserting a metal wire piece into the slot between two teeth on the toothed driving belt to simulate the looseness of the driving belt. The inserted metal wire piece was cut into the same dimensions in size as the slot between the belt teeth so that the slot was perfectly filled with the metal wire piece. Then the metal wire piece was tied on the belt with a thin flexible tape.

The 3D printer was run with and without the fault seeded driving belt to produce ten sets of bolt and nut (five sets for each condition). Individual run took about 28 minutes to print one set of bolt and nut. For sample consistency, a total of six heterodyned AE data samples were recorded for 10 seconds at pre-specified time locations from each run. The data acquisition procedure for the seeded fault test is depicted with a flowchart in Figure 5.

![Figure 4. Seeded fault on toothed belt.](image)

![Figure 5. Data acquisition procedure.](image)
were not printed up to the required precision due to the driving belt fault in the 3D printer.

Figure 6. 3D outputs from the healthy and the faulty 3D printers.

4. RESULTS

This section covers the 3D printer fault diagnostic results from the AE and PE strain sensor based technique. Section 3.1 explains AE signal analysis results and Section 3.2 the PE strain sensor signal analysis results.

4.1. AE Signal Analysis Results

The AE signal analysis results for the seeded fault tests conducted on the 3D printer test rig are provided in this section. Figure 7 shows the spectrums of AE data samples. By examining the spectrums in Figure 7, two different frequency regions were chosen for the low pass and narrow band pass filters: low frequency region up to 20 kHz and narrow band frequency around 3906 Hz. As shown in Figure 7, a remarkably high peak was observed within low pass range from all of AE samples. These peaks are specifically located at 3906 Hz. So a narrow band pass filter with a band width of 3906±3 Hz around the peak frequency location was chosen.

In Figure 8, RMS result from the low pass filter is provided. The resulting RMS of the heterodyned AE sample showed clear separation between healthy and faulty 3D printing condition. In Figure 8(a), RMS values at each sample location and trial are presented. In Figure 8(b), the averaged RMS values with a 95% confidence interval at each sample location are provided.

In Figures 9 to 12, CIs from the narrow band filtered AE signals are provided. Among all the CIs tested, majority of those that show a clear separation between the healthy and faulty 3D printing conditions were computed from narrow band filtered signals. Note that the bandwidth of this narrow band is in the low frequency filter region. A clear separation between the healthy and faulty 3D printing conditions with a 95% statistical significance can be observed for the following AE based CIs: RMS, NB-RMS, NB-P2P, AM-RMS, and AM-P2P.

Figure 7. Spectrum of 3D printer AE signal samples: (a) healthy, (b) faulty.

Figure 8. RMS of healthy and faulty low pass filtered results: (a) all data, (b) average with 95% confidence interval.

Figure 9. RMS from narrow band pass filtered result: (a) all data, (b) average with 95% confidence interval.
4.2. PE Strain Signal Analysis

In processing the PE strain sensor signals to extract CIs for the 3D printer fault detection, a similar strategy used by Kiddy et al. (2011) was applied. In their study, PE strain signals were divided into two parts based on their frequency: low frequency part and high frequency part. Actual damage detection was performed on the high frequency part of the strain sensor data using condition indicators. Thus, in this research, high pass filtered PE strain signals were used to compute the CIs. In search for the appropriate filter band, the fast kurtogram (Antoni, 2007) was applied to exam the impulsivity locations of PE strain signals collected from the healthy 3D printers.

Provided in Figure 13, a sample fast kurtogram result from the healthy 3D printer is displayed. The area in dark red color indicates the location of impulsivity. Statistical result of the fast kurtogram is summarized in Table 2. The 90% and 95% trimmed mean indicate that the impulsivity of PE sensor signals are located around 3.3 kHz to 4.2 kHz, respectively. Thus, a high pass band above 3 kHz was selected. Here a $X\%$ trimmed mean is the average of the data after $(100 - X)\%$ of the outliers are removed.

4.3. Results Summary

The 3D printer seeded fault detection results using both the AE sensor and PE strain sensor can be summarized in Table 3.

</tbody>
</table>

As shown in Table 2, for both the AE sensor and PE strain sensor used in the case study for 3D printer fault detection, a sampling rate of 100 kHz was used for data acquisition. For AE sensor signals, two band pass filters were used: a low pass filter and a narrow band filter. When the low pass filter was used, RMS provided the best performance and was able to detect the fault. When a narrow band filter was used, the following CIs were able to detect the fault: NB-RMS, NB-P2P, AM-RMS, and AM-P2P. For PE strain sensor signals, a high pass filter was used and only one CI, RMS, was able to detect the fault.

It has to be pointed out that the 3D printer fault was detected right after the first sample data was collected by both the AE and PE strain sensor in the seeded fault test. In real AM application, it can take up to several days to print out a product by a 3D printer. Therefore, significant amount of manufacturing time, materials, and cost can be saved and the quality of the product can be assured if a 3D printer fault can be detected and the printer be stopped days before it finishes printing the defective product.

5. Conclusions

In this paper, an investigation into the feasibility of PHM based AE and PE strain signal analysis techniques for 3D printer fault detection and quality control was reported. The presented PHM approach was developed using two types of NDE/NDT sensors: AE sensor and piezoelectric strain sensor. A seeded driving belt fault on a fused filament fabrication desktop 3D printer was used to validate the feasibility of the PHM approach in the case study. For the AE signal analysis in particular, a high peak in the frequency domain was detected and a narrow band pass filter around the peak was used to extract multiple condition indicators to detect the fault. On the other hand, in the PE strain analysis, the fast kurtogram was used to determine the proper high-pass filter band to obtain high frequency components to obtain effective fault detection CIs. The results have shown that the driving belt seeded looseness fault could be detected by both of the AE and PE strain sensor analysis methods. The methods presented in this paper could be extended to other potential 3D printing faults such as material feed or additional mechanical component faults.
